## Notion of risk decomposition

Context : usual supervised learning.

- ▶ empirical risk of estimator  $f$  :  $R_n(f)$  (random variable)
- ▶ risk of estimator  $f$  :  $R(f)$  (real number).
- ▶ dataset  $D_n$ .

We would like to interpret the risk of any estimator.

## Convergence of empirical risk

We fix  $f \in H$  (hypothesis space). We assume that the samples  $(x_i, y_i)$  are i.i.d, with the distribution of  $(X, Y)$ , noted  $\rho$ . Then, according to the law of large numbers, under some assumptions (for instance, if the empirical risks are bounded), we have that in probability :

$$\lim_{n \rightarrow +\infty} R_n(f) = R(f) \quad (1)$$

The empirical risk of a fixed  $f$  converges to its real risk.

## Notion of risk decomposition

We would like to compare  $R(g)$ , for some estimator  $g$ , to  $R^* = R(f^*)$ ,  $f^*$  being the Bayes estimator.

## First decomposition

- ▶  $f^*$  : Bayes predictor
- ▶  $F$  : Hypothesis space
- ▶  $g$  : some predictor ( $\in F$ ).

$$R(g) - R^* = \left( R(g) - \inf_{f \in F} R(f) \right) + \left( \inf_{f \in F} R(f) - R^* \right) \quad (2)$$

## First decomposition

- ▶  $f^*$  : Bayes predictor
- ▶  $F$  : Hypothesis space
- ▶  $g$  : some predictor
- ▶  $f_n$  : empirical risk minimizer

Most of the time, we will be interested in such a decomposition for the learned estimator, e.g. the empirical risk minimizer  $f_n$ . Now,  $R(f_n)$  is a **random variable** !

$$E[R(f_n)] - R^* = \left( E[R(f_n)] - \inf_{f \in F} R(f) \right) + \left( \inf_{f \in F} R(f) - R^* \right) \quad (3)$$

## Underfitting and overfitting

**Approximation error (bias)** : depends on  $f^*$  and  $F$ , not on  $f_n$ ,  $D_n$ .

$$\inf_{f \in F} R(f) - R^* \geq 0$$

**Estimation error (variance, fluctuation error, stochastic error)** : depends on  $D_n$ ,  $F$ ,  $f_n$ .

$$E(R(f_n)) - \inf_{f \in F} R(f) \geq 0$$

- ▶ too small  $F$  : underfitting (large bias, small variance)
- ▶ too large  $F$  : overfitting (small bias, large variance)

## Deterministic bound on the estimation error

We consider the best estimator in hypothesis space  $F$ .

$$f_a = \arg \min_{h \in F} R(h)$$

**Exercise 1:** Let us show that

$$R(f_n) - R(f_a) \leq 2 \sup_{h \in F} |R(h) - R_n(h)| \quad (4)$$

# Deterministic bound on the estimation error

$$f_a = \arg \min_{h \in F} R(h)$$

$$\begin{aligned} R(f_n) - R(f_a) &= (R(f_n) - R_n(f_n)) \\ &\quad + (R_n(f_n) - R_n(f_a)) \\ &\quad + (R_n(f_a) - R(f_a)) \end{aligned} \tag{5}$$

But by definition  $f_n$  minimizes  $R_n$ , so  $(R_n(f_n) - R_n(f_a)) \leq 0$ .

## Deterministic bound on the estimation error

$$R(f_n) - R(f_a) \leq 2 \sup_{h \in F} |R(h) - R_n(h)| \quad (6)$$

Later in the course, based on **concentration inequalities** we will further build on this result and prove a probabilistic bound of the form

$$R(f_n) - R(f_a) \leq \frac{C}{\sqrt{n}} \quad (7)$$

(remember that by definition  $0 \leq R(f_n) - R(f_a)$ )

## Approximate solution

- ▶ In machine learning, it is often not necessary to find the actual minimizer of the empirical risk , as there is an estimation error of  $\mathcal{O}(\frac{1}{\sqrt{n}})$ . [Bottou and Bousquet, 2009, ]
- ▶ We can use an approximate solution  $\hat{f}_n$ , such that

$$R_n(\hat{f}_n) \leq R_n(f_n) + \rho \quad (8)$$

with  $\rho$  a predefined tolerance.

- ▶ This important because in large-scale ML, the **computation time** needs to be optimized.

## Approximate solution

This gives a new risk decomposition :

$$\begin{aligned} E[R(\hat{f}_n)] - R^* &= \left( E[R(\hat{f}_n)] - E[R(f_n)] \right) \\ &\quad + \left( E[R(f_n)] - \inf_{f \in F} R(f) \right) \\ &\quad + \left( \inf_{f \in F} R(f) - R^* \right) \end{aligned} \tag{9}$$

$$\begin{aligned} E[R(\hat{f}_n)] - R^* &= \left( E[R(\hat{f}_n)] - E[R(f_n)] \right) \\ &\quad + \left( E[R(f_n)] - \inf_{f \in F} R(f) \right) \\ &\quad + \left( \inf_{f \in F} R(f) - R^* \right) \end{aligned} \tag{10}$$

$E[R(\hat{f}_n)] - E[R(\tilde{f}_n)]$  is the **optimization error**.

To conclude, we have :

- ▶ an approximation error
- ▶ an estimation error
- ▶ an optimization error

Risks and risk decompositions

## Probabilistic modelling

Classification and regression trees

- Decision trees

- Construction of a decision tree

- Tree pruning

Ensemble learning

- Bagging

- Random forest

- Boosting

# Context

We are given a set of observations  $\{y_1, \dots, y_n\} \in \mathcal{Y}$  that we assume are generated i.i.d from an unknown distribution. We look for a **probabilistic model** that explains well the data. We could use this model to predict well new data, that would be statistically similar to the observed ones.

## Density estimation

We will consider **parametric models** for density estimation.

### Definition

Parametric model

Let  $\Theta \subset \mathbb{R}^p$ . A parametric model  $\mathcal{P}$  is a set of probability distributions on  $\mathcal{Y}$ , indexed by elements of  $\Theta$ .

$$\mathcal{P} = \{p_\theta | \theta \in \Theta\}$$

Examples :

- ▶ Bernoulli model (parameter  $p$ )
- ▶ Gaussian model (parameter  $(\mu, \sigma)$ )
- ▶ Binomial model (parameter  $(n, p)$ )

# Objective

If we assume that the data were generated from some  $p_{\theta^*} \in \mathcal{P}$ , with a unknown parameter  $\theta^*$ , our goal is to find a good estimation of  $\theta$ . If the data are indeed generated by a distribution in  $\mathcal{P}$ , the problem is said to be **well specified**. Otherwise, the problem is said to be **misspecified**.

## Definition

### Likelihood

Let  $\mathcal{P} = \{p_\theta, \theta \in \Theta\}$  be a parametric model.

Given  $y \in \mathcal{Y}$ , the **likelihood** is the function :

$$\theta \mapsto L(\theta|y) = p_\theta(y) \quad (11)$$

Given  $D_n = (y_1, \dots, y_n)$ , the likelihood  $L(.|D_n)$  is the function :

$$\theta \mapsto L(\theta|D_n) = \prod_{i=1}^n p_\theta(y_i) \quad (12)$$

The **maximum likelihood estimator** (MLE) is the parameter  $\theta$  that maximises the likelihood :

$$\hat{\theta}_n \in \arg \max_{\theta \in \Theta} (L(\theta|D_n)) \quad (13)$$

## Remarks

- ▶ Since the samples  $y_i$  are assumed to be independent, the likelihood corresponds to the probability of observing the dataset according to  $p_\theta$ .
- ▶ We often maximise the log of the likelihood, as it is easier to differentiate a sum. Since log is an increasing function, the MLE is also the maximiser of the log of  $L$ .

## Example 1

**Exercice 2 :** We observe the data  $(1, 0)$ . We model these data with a Bernoulli distribution of parameter  $p$ .

- ▶ What is the likelihood of these observations as a function of  $p$ ?
- ▶ What is the value  $\hat{p}$  that maximizes this likelihood?

## Example 2

**Exercise 3:** We observe the data  $(1, 0, 1)$  (same hypotheses)

- ▶ What is the likelihood of these observations as a function of  $p$ ?
- ▶ What is the value  $\hat{p}$  that maximizes this likelihood?

## Example 3

We observe the data  $(2.5, 3.5)$ . We assume that these data come from a normal law of parameters  $\mu$  and  $\sigma$ .

$$\begin{aligned} L &= p(2.5|\mu, \sigma)p(3.5|\mu, \sigma) \\ &= \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{1}{2}(\frac{2.5-\mu}{\sigma})^2} \times \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{1}{2}(\frac{3.5-\mu}{\sigma})^2} \end{aligned} \quad (14)$$

We want to show that the likelihood is maximum for :

- ▶  $\hat{\mu} = \frac{2.5+3.5}{2}$
- ▶  $\hat{\sigma}^2 = \frac{(2.5-\hat{\mu})^2 + (3.5-\hat{\mu})^2}{2}$

## ERM

In the context of density estimation, we can define a loss function as the **negative log-likelihood**.

$$\Theta \times \mathcal{Y} \mapsto -\log(p_{\theta}(y))$$

Given this loss, the risk writes :

$$R(\theta) = E_Y[-\log(p_{\theta}(y))]$$

and the empirical risk :

$$R_n(\theta) = -\frac{1}{n} \sum_{i=1}^n \log(p_{\theta}(y_i))$$

The MLE is then also the empirical risk minimizer.

## KL divergence

The Kullback-Leibler divergence is a quantity used to compare two probability distributions.

### Definition

Kullback-Leibler divergence

Given two distributions  $p$  and  $q$ , the KL divergence from  $p$  to  $q$  is defined as :

$$KL(p||q) = E_{Y \sim p} \left[ \log \frac{p(Y)}{q(Y)} \right]$$

### Lemma

*If the data are generated by  $p_{\theta^*}$ , then  $KL(p_{\theta^*}||p_{\theta})$  is the excess risk of  $p_{\theta}$ , with the negative log-likelihood loss.*

## Link with supervised learning methods

Probabilistic modelling can provide an interesting interpretation of several supervised learning methods, such as :

- ▶ logistic regression
- ▶ ordinary least squares

In a supervised learning context, it is important to note that we replace the likelihood  $p_{\theta}(y)$  by a **conditional** likelihood  $p_{\theta}(y|x)$  (conditional modelling).

$$R_n(\theta) = -\frac{1}{n} \sum_{i=1}^n \log (p_{\theta}(y_i|x_i)) \quad (15)$$

## Link with logistic regression

We consider a binary classification problem, with  $\mathcal{Y} = \{0, 1\}$ .

Let us now consider the probabilistic model such that

$$p_{\theta}(1|x) = \sigma(\theta^T x)$$

Equivalently, this model can be written (remember that  $y = 0$  or  $y = 1$ )

$$p_{\theta}(y|x) = (\sigma(\theta^T x))^y (1 - \sigma(\theta^T x))^{1-y} \quad (16)$$

**Exercise 4:** Show that the parameter  $\theta$  with maximum likelihood is the logistic regression estimator  $\theta_{logit}$  (cross entropy version).

$$\begin{aligned}R_n(\theta) &= -\frac{1}{n} \sum_{i=1}^n \log(p_\theta(y_i|x_i)) \\&= -\frac{1}{n} \sum_{i=1}^n \log\left((\sigma(\theta^T x_i))^{y_i} (1 - \sigma(\theta^T x_i))^{1-y_i}\right) \\&= -\frac{1}{n} \sum_{i=1}^n y_i \log\left(\sigma(\theta^T x_i)\right) + (1 - y_i) \log\left(\sigma(-\theta^T x_i)\right) \quad (17) \\&= \frac{1}{n} \sum_{i=1}^n y_i \log\left(1 + e^{\theta^T x_i}\right) + (1 - y_i) \log\left(1 - e^{\theta^T x_i}\right) \\&= \frac{1}{n} \sum_{i=1}^n l(\theta^T x_i, y_i)\end{aligned}$$

Risks and risk decompositions

Probabilistic modelling

Classification and regression trees

- Decision trees

- Construction of a decision tree

- Tree pruning

Ensemble learning

- Bagging

- Random forest

- Boosting

# CART

- ▶ Segmentation method (partitionnement récursif), **binary splits**.
- ▶ First algorithm : **CART** (classification and regression tree, Breiman, 1984) [Breiman et al., 2017]

## Example dataset : fishes

## Fish dataset

# Fish dataset

## Example tree

## Splitting nodes

Each split should lead to more **homogeneous** nodes (in a sense that is to be formally defined)

## Splitting nodes

A leaf node corresponds to a predicted value.

Decision trees can be used for regression. In that case, the prediction is **piecewise constant**. It can be seen as a form of local averaging.

## Construction of a tree

A split node corresponds to :

- ▶ a segmentation variable  $V$
- ▶ a segmentation value / threshold if  $V$  is quantitative. If  $V$  is a class, it is a two-fold partitionning of the set of classes.

The construction of a tree requires a criterion to :

- ▶ choose the segmentation variable and value
- ▶ decide when a node is terminal (leaf node)
- ▶ associate a prediction value to all leaf nodes

## Homogeneity

We want the homogeneity in the child nodes to be greater than in the parent node. Equivalently, we can define a non-negative heterogeneity function  $H$  that describes each node and that must be :

- ▶ 0 if the node is homogeneous (only one class or one output value is represented in this node)
- ▶ maximal if the values of  $y$  are uniformly distributed within the node.
- ▶ if  $H(L)$  is the value of  $H$  for the left child node (and  $H(R)$  for the right one), then the segmentation should minimize

$$H(L) + H(R) \tag{18}$$

## Homogeneity criterion for regression

In the case of regression,  $\mathcal{Y} = \mathbb{R}$  and the heterogeneity  $H(n)$  of node  $n$  is its empirical variance :

$$H(n) = \frac{1}{|n|} \sum_{i \in n} (y_i - \bar{y}_n)^2 \quad (19)$$

## Homogeneity criterion for classification

In the case of classification,  $\mathcal{Y} = [1, \dots, L]$  and several criteria exist.

## Homogeneity criterion for classification : entropy (information gain)

- ▶ We use the convention that  $0 \log(0) = 0$
- ▶  $p_n^l$  is the proportion of class  $l$  in node  $n$ .

The **entropy** writes :

$$H(n) = - \sum_{l=1}^L p_n^l \log(p_n^l) \quad (20)$$

**Exercise 5 :** What are the maximum and minimum values of the entropy ?

## Homogeneity criterion for classification : Gini impurity

The Gini impurity writes :

$$H(n) = \sum_{l=1}^L p_n^l (1 - p_n^l) \quad (21)$$

## Homogeneity criterion for classification : Gini impurity

The Gini impurity writes :

$$H(n) = \sum_{l=1}^L p_n^l (1 - p_n^l) \quad (22)$$

**Exercise 6 :** Interpret the meaning of the Gini impurity in terms of probabilities, assuming that we predict according to the proportions  $p_n^l$ .

- ▶  $Y_{pred}$  is the random variable representing this prediction (proportional)
- ▶  $Y$  is the random variable representing the class, in this node (empirical distribution)

$$\begin{aligned} P(Y_{pred} \neq Y) &= \sum_{l=1}^L P(Y_{pred} \neq Y | Y = l) P(Y = l) \\ &= \sum_{l=1}^L \left(1 - P(Y_{pred} = Y | Y = l)\right) P(Y = l) \quad (23) \\ &= \sum_{l=1}^L (1 - p_n^l) p_n^l \end{aligned}$$

## Homogeneity criterion for classification : Gini impurity

$$H(n) = \sum_{l=1}^L p_n^l (1 - p_n^l) \quad (24)$$

If we predict the classes in node  $n$  according to the proportions of the labels in  $n$ , then the Gini impurity is the probability of making a mistake, given that we are in node  $n$ .

## Homogeneity criterion for classification : misclassification probability

$$H(n) = 1 - \max_l (p_n^l) \quad (25)$$

If we predict the most represented class in  $n$ , then this is the misclassification probability.

## Prediction for a leaf node

- ▶ **regression** : predict the average value in the node
- ▶ **classification** : several possibilities
  - ▶ most represented class in the node
  - ▶ most probable class *a posteriori* if the *a priori* probabilities are known (Bayesian probabilities)
  - ▶ class that costs the less in case of missclassification

# Pruning

- ▶ If the segmentation is not restricted, the tree can fit the training dataset perfectly (overfitting).
- ▶ learning would then be highly dependent on the choice of the training dataset, leading to **instability**.
- ▶ To avoid it, **pruning** (élaguage) is used : it consists in restricting the size of the tree (and can be seen as an equivalent to regularization like in ridge regression or logistic regression).

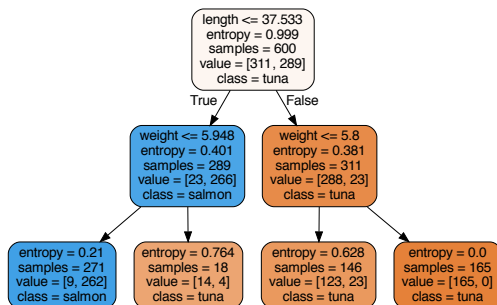

## Pre-pruning by restricting divisions

We can impose

- ▶ minimum impurity decrease
- ▶ a minimum number of samples in a leaf node
- ▶ a minimum number of samples to authorize splitting a node

## Simulation : fish dataset, max depth=1

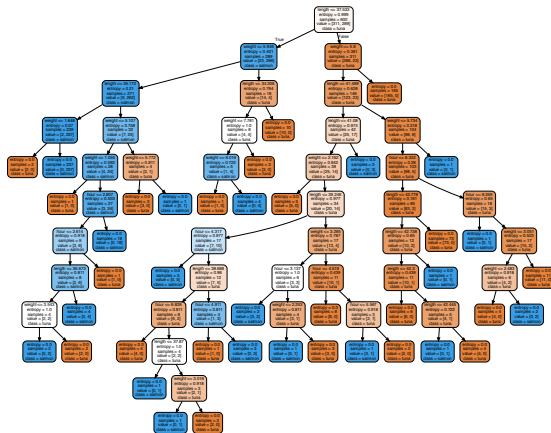

# FTML

## Classification and regression trees

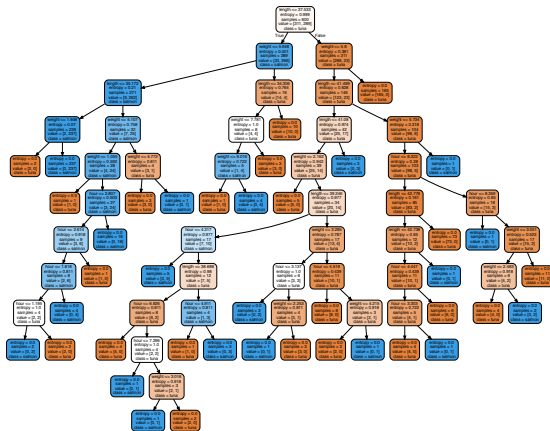

### Tree pruning

# FTML

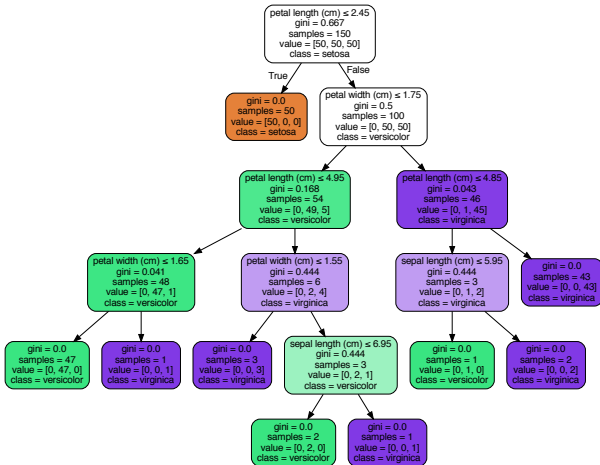

## Classification and regression trees

### Tree pruning

## Overfitting : Iris dataset, max depth=34

## Avoiding overfitting : Iris dataset

Figure – Avoid overfitting with pre-pruning. In this case, impose a minimum impurity decrease of 0.1

## Post-pruning

It is also possible to prune after the construction of a large tree.

## Remarks on decision trees I

- ▶ Decision trees do not require hypotheses on the distribution of de features.
- ▶ Feature selection is integrated in the algorithm, so they might be relevant in a situation with many features (variables explicatives)
- ▶ A segmentation is invariant to a monotonic change in a feature. It is thus robust to outliers or to very asymmetrical distributions.
- ▶ Decision trees allow a straightforward **interpretation** of the model.

## Remarks on decision trees II

- ▶ Decision trees are greedy : they might find a local minimum
- ▶ they are hierarchical : a bad choice in a segmentation at the top of the tree propagates in the whole tree
- ▶ Hence their instability and sensibility to the choice of the training set.

Risks and risk decompositions

Probabilistic modelling

Classification and regression trees

Decision trees

Construction of a decision tree

Tree pruning

Ensemble learning

Bagging

Random forest

Boosting

# Ensemble learning

- ▶ *Bagging* and *boosting* are methods that combine estimators (in parallel or sequentially)
- ▶ they are often applied to decision trees
- ▶ they reach state-of-the-art performance in several supervised learning tasks [Fernández-Delgado et al., 2014]
- ▶ they are an active area of research (both theoretically and for practical applications).

<https://scikit-learn.org/stable/modules/ensemble.html>

## Aggregating to reduce the variance

- ▶ usual setup : input space  $\mathcal{X}$ , output space  $\mathcal{Y}$ .
- ▶ we note  $z_b$  a dataset sampled from the unknown distribution  $\rho$ . If we sample  $b$  different datasets,  $b \in [1, B]$ ,

$$z_b = \{(x_{1b}, y_{1b}), \dots (x_{nb}, y_{nb})\} \quad (26)$$

- ▶ we note  $\hat{f}_{z_b}$  the estimator obtained after learning with  $z_b$ .

## Aggregate to reduce the variance

- ▶ we note  $z_b$  a dataset sampled from the unknown distribution  $\rho$ . If we sample  $b$  different datasets,  $b \in [1, B]$ ,

$$z_b = \{(x_{1b}, y_{1b}), \dots (x_{nb}, y_{nb})\} \quad (27)$$

- ▶ we note  $\hat{f}_{z_b}$  the estimator obtained after learning with  $z_b$ .

**Aggregating** consists in using as an estimator :

- ▶ for regression

$$\hat{f}_B = \frac{1}{B} \sum_{b=1}^B \hat{f}_{z_b} \quad (28)$$

- ▶ for classification

$$\hat{f}_B(x) = \arg \max_j |\{b, \hat{f}_{z_b}(x) = j\}| \quad (29)$$

## Bootstrapping and bagging

If  $B$  is large, it is not possible to sample  $B$  independent datasets with  $n$  samples, from a finite dataset.

**Bootstrapping** consists in sampling  $B$  times a sample dataset with  $n$  elements **with replacement**.

**Bagging** is the combination of bootstrapping and aggregating.

## Out-of-bag error

Vocabulary : for an observation  $(x_i, y_i)$ , the **out-of-bag error** is the mean error on this observation among the estimators that were trained on a bootstrap dataset **not** containing it.

# Simulation

## Individual estimators

Figure – Estimator used in the averaging

## Individual estimators

Figure – Other estimator used in the averaging

## Possible issues

- ▶ number of trees to compute ( $B$ ) in order to have a stable out-of-bag error.
- ▶ need for storing all the base estimators
- ▶ the final estimator is a *black-box* model.

## Random forest

- ▶ Random forest [Breiman, 2001] is a bagging method with binary CART estimators, with additional randomness added to the choice of segmentation variables.
- ▶ the goal is to increase the **independence** between the base trees.
- ▶ although the theoretical properties of random forest are not yet fully understood, it is an important benchmark in supervised learning (but for instance not when the problem can be solved in a linear way).

## Variance of an average : independent variables

Recall that if  $(X_k)_{k \in \mathbb{N}}$  is a sequence of i.i.d. real variables that have a moment of order 2, and hence a variance  $\sigma^2$ , and an expected value of  $m$ . Then if  $S_B = \frac{1}{B} \sum_{i=1}^B X_i$

$$\begin{aligned} \text{Var}(S_B) &= \sum_{i=1}^B \text{Var}\left(\frac{1}{B} X_i\right) \\ &= \frac{1}{B^2} \sum_{i=1}^B \text{Var}(X_i) \\ &= \frac{\sigma^2}{B} \end{aligned} \tag{30}$$

## Variance of the average : correlated variables

However, if the  $X_i$  are identically distributed but correlated with correlation  $c$ , then we admit that

$$\text{Var}(S_B) = c\sigma^2 + \frac{1-c}{B}\sigma^2 \quad (31)$$

Random forest diminishes  $c$  by adding some randomness in the choice of the segmentation variables.

## Random forest

Let  $d$  be the number of features. Let  $m \leq d$  be an integer.

**Result:** Random forest estimator

**for**  $b \in [1, B]$  **do**

    Sample a bootstrap dataset  $z_b$ ;

    Estimate  $\hat{f}_{z_b}$  with **randomization** of the variables. The search of the optimal segmentation is done on  $m$  randomly sampled variables.;

**end**

**return**  $\hat{f}_B$

$$\hat{f}_B = \frac{1}{B} \sum_{b=1}^B \hat{f}_{z_b} \quad (32)$$

**Algorithm 1:** Random forest

## Remarks on random forest

- ▶ With random forest, it is possible to use a more brutal pruning (for instance using only trees of depth 2)
- ▶ To tune  $m$ , heuristics are used. Common ones include :
  - ▶  $m = \sqrt{d}$  for classification ( $d$  is the number of features)
  - ▶  $m = d/3$  for regression
  - ▶ cross validation.

## Example in 1D

Bayes risk:  $7.00\text{E-}01$

# Estimators

## Importance of the variables

Although the obtained estimator is hard to interpret, we can still study the statistical importance of variables for the prediction.

## Mean decrease accuracy

Consider a variable  $j$ . For a given tree  $b$

- ▶ compute the out-of-bag error.
- ▶ shuffle the values of  $j$  in the out-of-bag sample.
- ▶ compute the new out-of-bag error
- ▶ store the decrease in prediction quality,  $D_j^b$ .

Average the  $D_j^b$  on  $b$  in order to measure the importance of the variable  $j$ .

# Boosting

- ▶ While bagging is a random method, **boosting** is an adaptive method.
- ▶ Boosting builds on *weak classifiers*, and like bagging, aggregates them, for instance with a **weighted sum**.
- ▶ However, the weak classifiers are built **sequentially**. The classifier  $b + 1$  adapts the classifier  $b$  by focusing on improving the prediction of incorrectly classified training samples.
- ▶ Several variants exists (in the weighting, loss function, aggregating method, etc).

# Adaboost

- ▶ Original boosting algorithm [Freund and Schapire, 1996]
- ▶  $\mathcal{Y} = \{-1, 1\}$  (but can also be adapted to a regression problem)
- ▶ Given the sample dataset  $z = \{(x_1, y_1), \dots (x_n, y_n)\}$ . We learn a **sequence of estimators**  $(\delta_m)_{m \in [1..B]}$  (often CART).

Initialize the weights  $w = \{w_i = \frac{1}{n}, i = 1..n\}$ ;

**for**  $m = 1..B$  **do**

Estimate  $\delta_m$  on the weighted dataset. Compute the error rate

$$\hat{\epsilon}_m = \frac{\sum_{i=1}^n w_i 1(\delta_m(x_i) \neq y_i)}{\sum_{i=1}^n w_i} \quad (33)$$

Compute the logit of  $\hat{\epsilon}_m$

$$c_m = \log \left( \frac{1 - \hat{\epsilon}_m}{\hat{\epsilon}_m} \right) \quad (34)$$

Update the weights

$$w_i \leftarrow w_i \exp \left( c_m 1(\delta_m(x_i) \neq y_i) \right) \quad (35)$$

**end**

$$\hat{\delta}_B = \text{sign} \left( \sum_{b=1}^B \delta_{z_b} \right) \quad (36)$$

return  $\hat{f}_B$

**Algorithm 2:** Adaboost for binary classification (adaptive boosting)

## Remarks

We need to enforce that  $c_m \geq 0$ . It is verified if  $\hat{\epsilon}_m \geq \frac{1}{2}$ .

$$c_m = \log \left( \frac{1 - \hat{\epsilon}_m}{\hat{\epsilon}_m} \right) \quad (37)$$

- ▶ It is experimentally shown that if the weak classifiers are *stump trees* (2 leaves), then adaBoost performs better than one given tree with a number of leaves equal to the number of iterations of adaBoost (hence a comparable computation time).
- ▶ A number of leaves  $q$  between 4 and 8 for the weak classifiers is often recommended.
- ▶ adaBoost can be adapted to multiclass classification and regression [Schapire, 2003].

# Gradient tree boosting

- ▶ differentiate with respect to the predictions of the tree (compute a gradient)
- ▶ approximate the gradient by a regression tree
- ▶ update the tree following this gradient.

# Gradient tree boosting

Initialize  $f_0 = \arg \min_z \sum_{i=1}^n l(y_i, z)$ ;

**for**  $m = 1..B$  **do**

    Compute  $r_{m_i} = -\frac{\partial l(y_i, f(x_i))}{\partial f(x_i)} (f = f_{m-1}), i \in [1, n]$

    Train a decision tree  $\delta_m$  on  $(x_i, r_{m_i})_{i \in [1, n]}$

    Compute  $\gamma_m$  minimizing

$$\sum_{i=1}^n l(y_i, f_{m-1}(x) + \gamma \delta_m(x_i)) \quad (38)$$

    Update the estimator

$$\hat{f}_m = \hat{f}_{m-1} + \gamma_m \delta_m \quad (39)$$

**end**

return  $\hat{f}_B$

## Algorithm 3: Gradient tree boosting

# Simulation

Gradient boosting regression  
number of estimators: 40  
max depth: 3  
test error:  $8.39\text{E-}01$   
Bayes risk:  $7.00\text{E-}01$

## Gradient tree boosting

Many parameter can be tuned :

- ▶ maximum depth of the estimators
- ▶ shrinkage  $\eta$  ( $\hat{f}_m = \hat{f}_{m-1} + \eta \gamma_m \delta_m$ , with  $0 \leq \eta \leq 1$ ). If  $\eta$  is low, e.g.  $\leq 0.1$ , it can lead to a slower convergence but might prevent overfitting.
- ▶ number of trees learned  $B$

<https://www.analyticsvidhya.com/blog/2016/02/complete-guide-parameter-tuning-gradient-boosting-gbm-python/>

It is necessary to experiment, read documentations, cross validate, use heuristics, etc.

## Extrem gradient boosting

- ▶ XGBoost : variant of gradient boosting, very efficient on several benchmarks [Chen and Guestrin, 2016]
- ▶ can exploit parallelization
- ▶ `https://xgboost.readthedocs.io/en/latest/parameter.html`
- ▶ `https://github.com/dmlc/xgboost`
